Key points

- The influences of subtropical Atlantic Ocean moisture on southern Africa precipitation are non-negligible, especially during droughts.
- Precipitation isotopes can identify drought mechanisms e.g., synoptic-scale (El Niño) versus mesoscale drought.
- Precipitation $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ are independent of precipitation type (stratiform vs. convective) in the study area.

This is the author's manuscript of the article published in final edited form as:

Abstract

Southern African climate is characterised by large precipitation variability and model precipitation estimates can vary by 70% during summer. This may be partly attributed to underestimation and lack of knowledge of the exact influence of the Atlantic Ocean on precipitation over the region. The current study models trajectories of precipitation events sampled from Windhoek (2012-2016), coupled with isotopes ($\delta^{18}\text{O}$, $\delta^2\text{H}$, $\delta^{17}\text{O}$, d and $\delta^{17}\text{O}-\delta^{18}\text{O}$) to determine key local drivers of isotope compositions as well as infer source evaporative conditions. Multiple linear regression analyses suggest that key drivers of isotope compositions (relative humidity, precipitation amount and air temperature) account for 47-53% of $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ variability. Surprisingly, precipitation $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ were independent of precipitation type (stratiform vs. convective) and this may be attributed to greater modification of stratiform compared to convective raindrops, leading to convergence of isotopes from these precipitation types. Trajectory analyses showed that 78% and 21% of precipitation events during the period originated from the Indian and South Atlantic Oceans, respectively. Although precipitation from the Atlantic Ocean was significantly enriched compared to that from the Indian Ocean ($p < 0.05$); d was similar, suggesting significant local modification (up to 55 % of d variability). Therefore, d may not be a conservative tracer of evaporation conditions at the source, at least for Windhoek. $\delta^{17}\text{O}-\delta^{18}\text{O}$ appeared a better alternative to d , consistent with trajectory analyses and appeared to differentiate El Niño from non El Niño droughts. Thus $\delta^{17}\text{O}-\delta^{18}\text{O}$ could be a novel tool to identify drought mechanisms.

Keywords: climate change, ecohydrology, HYSPLIT, Namibia, rainfall, stable isotopes

1 Introduction

The climate of southern Africa, defined as the land area bound by the region 15°S–35°S; 12.5°E–42.5°E, is complex and involves the interaction of several factors that alternate in importance [Allan *et al.*, 2003; Reason and Rouault, 2002; Richard *et al.*, 2000]. Traditionally, Atlantic influences on southern African precipitation have been downplayed and this could be attributed to data paucity, lack of awareness of the complexities of the atmosphere-ocean coupling and associated tropical-extratropical interactions as well as perceptions that Atlantic influences were secondary to those from the Indian or Pacific Oceans (ENSO) [Reason *et al.*, 2006]. Therefore, precipitation over southern Africa has been associated with sea surface temperatures (SST) from the Indian Ocean [D'Abreton and Lindesay, 1993; Reason and Mulenga, 1999]. However, there is growing consensus that the South Atlantic Ocean may play a significant role on climate in the region, although the exact influences are unknown [Reason *et al.*, 2006]. Given this uncertainty in moisture origins, it is not surprising that model estimates of precipitation over the region vary depending on a model's representation of the Angola Low, a regional circulation feature which can account for as much as 60% of the inter-model variability [Munday and Washington, 2017]. The ability to capture this ocean-atmospheric circulation feature might drive the disagreement between models. Therefore, despite the tight coupling between precipitation and society in southern Africa [Conway *et al.*, 2015], our knowledge of precipitation patterns and their climate controls for the region are limited [Reason *et al.*, 2006].

Stable isotopes of hydrogen and oxygen ($\delta^2\text{H}$ and $\delta^{18}\text{O}$) are unique environmental tracers that can be used to understand dynamics and processes in hydrology, geology, ecology and climate research [Gat, 1996; Stumpp *et al.*, 2014; Zhao *et al.*, 2012]. However, relatively few studies across Africa have applied stable isotopes of precipitation to climate research. Although global isoscapes reproduce reasonably well the global distribution of mean annual isotope contents of modern precipitation [Risi *et al.*, 2010; Werner *et al.*, 2011], they do not explain observed seasonal or inter-annual variations at a regional or local scale [Field, 2010; Lee *et al.*, 2007; Risi *et al.*, 2010; Schmidt *et al.*, 2005; Vuille *et al.*, 2003] and do not down-scale well in data scarce regions [Kaseke *et al.*, 2016; Terzer *et al.*, 2013]. Furthermore, multi-scale influences on the isotopic composition of precipitation do not conform well to univariate regression analysis in mid-latitude and subtropical locations [Alley and Cuffey, 2001; Fricke and O'Neil, 1999; Sturm *et al.*, 2010]. However, event-scale studies capture day-to-day synoptic variation that may be lost or diluted in monthly samples [Liu *et al.*, 2010; Noone and Simmonds, 2002]. Therefore, event-scale comparisons with aggregated data may help define underlying uncertainties in relationships between the isotopic composition of precipitation and climate variables [Soderberg *et al.*, 2013].

The moisture that eventually becomes precipitation is derived primarily from the oceans and/or evapotranspiration from the terrestrial surface [Sjostrom and Welker, 2009]. Therefore, traditional approaches have suggested air-mass history may influence the isotopic composition of precipitation [Dansgaard, 1964]. In addition to $\delta^2\text{H}$ and $\delta^{18}\text{O}$, d-excess defined as $d = \delta^2\text{H} - 8 \times \delta^{18}\text{O}$ [Dansgaard, 1964] has been used to determine evaporative conditions [Merlivat and Jouzel, 1979]. However, recent work suggests d may not be a true conservative tracer of evaporation conditions [Lai and Ehleringer, 2011; Welp *et al.*, 2012; Zhao *et al.*, 2014]. Until recently, it was assumed that $\delta^{17}\text{O}$ in precipitation did not carry any additional information to that of $\delta^{18}\text{O}$ [Angert *et al.*, 2004]. However, recent work indicates that $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ is independent of temperature and can be used to differentiate fractionation processes [Angert *et al.*, 2004; Kaseke *et al.*, 2017]. Therefore, $\delta^{17}\text{O}$ -excess ($^{17}\Delta$), $^{17}\Delta = \delta^{17}\text{O} - 0.528 \times \delta^{18}\text{O}$, could be a conservative tracer of humidity changes at the vapor source origin

and complement $\delta^{18}\text{O}$, $\delta^2\text{H}$ and d [Angert *et al.*, 2004; Barkan and Luz, 2007, Tian *et al.*, 2018]. In addition, air mass trajectories have been used to explain precipitation isotope variations in North America [Burnett *et al.*, 2004; Sinclair *et al.*, 2011; Sjoström and Welker, 2009], Europe [Baldini *et al.*, 2010; Gat and Carmi, 1970], Asia [Fudeyasu *et al.*, 2011; Liu *et al.*, 2011], Australia [Barras and Simmonds, 2009; Barras and Simmonds, 2008] and Africa [Lewis *et al.*, 2010; Soderberg *et al.*, 2013]. However, despite the complexities of southern African climate, we are not aware of any studies that have investigated the influence of atmospheric trajectories on southern African precipitation isotope compositions. We are also not aware of any studies that have reported $\delta^{17}\text{O}$ values in precipitation for the region. Using a four-year (2012-2016) precipitation dataset, the objectives of this study were thus to determine storm-to-storm isotopic variability and composition ($\delta^{18}\text{O}$, $\delta^2\text{H}$, $\delta^{17}\text{O}$) of precipitation in Windhoek (Namibia), identify the local controls of precipitation isotopes, apply trajectory analysis to determine vapor source origins and $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ relationships to infer evaporation conditions at the source region. The observation period covered three drought years of which two occurred during the 2014-2016 El Niño Southern Oscillation (ENSO) event. This provided the opportunity to test whether novel $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ techniques could be used to differentiate different types of droughts. We are not aware of any isotope studies that have done this, although a few have focused exclusively on isotope compositions and variability during ENSO events [Sánchez-Murillo *et al.*, 2017].

[Figure 1 here]

2 Materials and Methods

2.1 Site description and sample collection

Namibia is located on the south-western tip of the African continent and the study site (22.6137° S and 17.09753° E, elevation 1720 m a.s.l) is located in the capital, Windhoek (3 133km²) (Fig. 1a). According to the Köppen Climate classification system, Windhoek is a hot semi-arid climate (*BSh*) characterised by hot wet summers and cool dry winters. Based on data from the Southern Africa Science Service Centre for Climate Change and Adaptive Land-use [SASSCAL] Windhoek weather station (22.5706° S and 17.0957° E, elevation 1722 m a.s.l), 2012-2016 had the following monthly meteorological characteristics: temperature range (-0.2–36.3°C), average temperature (20.7°C), relative humidity (RH) range (0.4-99.6%) and average RH (29.5%) (Fig. 1b and Fig. 1c). Because precipitation is highly seasonal and precipitation events are concentrated between October and April [Lu *et al.*, 2016; Sturm *et al.*, 2009]), our analyses were based on the hydrologic year (October to September). Windhoek has not experienced any significant changes in precipitation intensity, frequency or total amount between 1998 and 2015 [Lu *et al.*, 2016], and because the current study falls within this timeframe, results should be comparable to this relatively long-term study.

A total of 109 discrete precipitation events were sampled during the observation period (Dataset S1). These precipitation events were matched based on the date of sampling to the SASSCAL weather data which showed 138 events during this period. This total excluded 42 precipitation events recorded by the SASSCAL weather station because there

were less than 0.2 mm per day and may have resulted in either insufficient sample for analyses or were localised events that did not occur at the sampling site. When possible, samples were collected immediately after the event or the next morning from a manual rain gauge and transferred into 15 ml Qorpak clear French square bottles with black phenolic polycone lined caps. The bottles were labelled with the appropriate site name, date and amount and stored at 5°C at the University of Namibia (UNAM) Windhoek campus. Samples were stored for about 6 months and either shipped or retrieved during field campaigns and transported to Indiana University-Purdue University Indianapolis (IUPUI) Ecohydrology lab for isotope analysis.

2.2 Isotope analysis

Isotope analysis was performed using the Triple Water Vapor Analyzer coupled to the Water Vapor Isotope Standard Source (WVISS) (Los Gatos Research Inc., Mountain View, CA, USA) with a reported precision of 0.2‰ $\delta^{18}\text{O}$, 0.8‰ $\delta^2\text{H}$ and 0.4‰ $\delta^{17}\text{O}$ similar to those reported elsewhere [Tian, 2016; Wang *et al.*, 2009]. Data was reported in δ notation relative to VSMOW-SLAP scale as

$$\delta = \left(\frac{R_{\text{sample}}}{R_{\text{VSMOW}}} - 1 \right) \times 10^3, \quad (1)$$

where R_{sample} and R_{VSMOW} are the molar ratios of heavy to light isotopes ($^2\text{H}/\text{H}$, $^{18}\text{O}/^{16}\text{O}$ or $^{17}\text{O}/^{16}\text{O}$) of the sample and international standard – Vienna Standard Mean Ocean Water (V-SMOW). However, it has been demonstrated that when dealing with high precision ratios in multiple systems a modified δ is preferred [Hulston and Thode, 1965; Luz and Barkan, 2005; Miller, 2002] hereafter designated as δ' and defined as

$$\delta'^{*}\text{O} = \ln(\delta + 1) = \ln\left(\frac{R_{\text{sample}}}{R_{\text{VSMOW}}}\right), \quad (2)$$

where $*\text{O}$ is either ^{17}O or ^{18}O .

We computed mean annual isotopic composition as arithmetic and weighted means, adapted from Kazmierz Rozanski and Gonfianttini [1993]:

$$\delta_{\text{Annual weighted}} = \sum_{\text{September}}^{\text{October}} \delta_{\text{Event}} \times \frac{\text{ppt}_{(\text{Event})}}{\text{ppt}_{(\text{Annual Total})}}, \quad (3)$$

where $\text{ppt}_{(\text{Event})}$ is the event precipitation amount and $\text{ppt}_{(\text{Annual Total})}$ is the annual total precipitation amount as defined by the hydrologic year.

2.3 Local meteoric water Lines (LMWLs)

Multiple statistical methods have been proposed to calculate the LMWL [Crawford *et al.*, 2014]. These methods include the unweighted and precipitation weighted versions of the ordinary least squares (OLSR), reduced major axis (RMA) and major axis (MA) regression models. However, because each method has its merits, we present all versions generated from the Local Meteoric Water Line Freeware programme [Crawford *et al.*, 2014], based on event samples (Table S1). A long term LMWL (2012-2016) was calculated and used as a reference for the site for comparisons to annual LMWLs from the same period. For statistical comparisons, the unweighted OLSR LMWL (annual and inter-annual) was adopted to

perform the analysis of covariance (ANCOVA). Similarly, annual $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ lines were calculated based on the unweighted OLSR to complement interpretation of the $\delta^{18}\text{O}$ - $\delta^2\text{H}$ LMWLs.

2.4 Precipitation classification: stratiform vs. convective

Tropical Rainfall Measuring Mission (TRMM) 2A25 V7 and Global Precipitation Measurement (GPM) 2AKu band satellite data products covering the study area during 2012-2016 were downloaded and analysed. Because the sampling site was located roughly in the centre of Windhoek, the sampling site was taken as the centre of a $0.5^\circ \times 0.5^\circ$ square centroid (3025 km^2) for data retrieval. The level 2 data products of TRMM and GPM have a temporal resolution of 16 orbits a day and a total of 24 satellite products showed precipitation over the area that corresponded to the Windhoek SASSCAL weather station. Data from both TRMM and GPM classify precipitation into three types: stratiform, convective and other. However, the third precipitation type 'other' was not encountered during our analyses and according to Aggarwal *et al.* [2016], it exists at higher levels and may not contribute significantly to precipitation near the surface. Therefore, for the purposes of this study we excluded the third classification. Average conditional precipitation rates were calculated for each event based on conditional stratiform and convective precipitation rates over the area. The stratiform fraction was defined as the ratio of stratiform rainfall to total conditional precipitation rates. Therefore, stratiform fraction as applied to this paper translates to 0% stratiform = 100% convective except during non-precipitation days and vice-versa.

2.5 Trajectory analyses

Analysis of discrete precipitation events permits the use of back trajectory models to determine source origins and inference of source evaporation conditions that may influence the isotopic composition of precipitation when coupled with secondary parameters such as *d*. We assumed similar meteorological conditions between the site and the National Botanic Research Institute Windhoek (NBRI), located 5 km away. This enabled the use of hourly meteorological data from the SASSCAL weather station located at the NBRI. Using this approach, 99 of the 109 precipitation events (91%) at the site were consistent with NBRI data, sampling dates and general volumes, providing an approximation of local meteorological conditions. The associated meteorological data and event times were then used to calculate the approximate cloud base height of each individual storm based on the lifted condensation level (LCL) [Lawrence, 2005; Romps, 2017]:

$$LCL = z + \left(20 + \frac{T-273.15}{5}\right) (100)(1 - RH), \quad (4)$$

where LCL is the cloud base height in metres, T is absolute temperature, RH is relative humidity ranging between 0 and 1 and z is the height where RH and T were measured.

Using LCL to determine the parcels origin height ($n = 99$), ten-day air mass back-trajectories were computed using the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model [Stein *et al.*, 2015] and meteorological data from the Global Data Assimilation System (GDAS1). Because LCL ranged between 83 and 2154 m above ground level, no trajectories were disqualified for reaching the top of the atmosphere. Global estimates for mean atmospheric moisture residence times range from 4 – 9 days [Läderach and Sodemann, 2016; Trenberth, 1998], while Miralles *et al.* [2016] estimates an optimal 6

day residence time for the Kalahari ecoregion. The average time for each trajectory from land intersection to Windhoek was about 140 hrs (~6 days), thus trajectory cluster analysis time was set at 140 hrs at six hour intervals. The total spatial variance (TSV) for this process was 30%, indicating there was no forcing and misclassification of cluster trajectories [Stein *et al.*, 2015]. Trajectory analyses in this study were used primarily to provide the spatial history of an air parcel.

2.6 Statistical analyses

Statistical analyses were performed in PAST 3 [Hammer, 2001] with parametric methods for normally distributed data and non-parametric methods for non-normally distributed data. Multiple linear regression analyses were performed in XLSTAT 2017 v 4, while trajectory cluster analysis was performed in HYSPLIT [Stein *et al.*, 2015]. All data pertaining to this study is provided as Dataset S1.

3 Results and discussion

3.1 Precipitation anomalies

Three of the four years under observation received below normal precipitation amounts and were classified as meteorological droughts, with the exception of 2013-2014 (Fig. 2 and Table S2). Based on the Oceanic Niño Index (ONI) [CPC, 2016], two of the three drought years (2014-2015 and 2015-2016) occurred during weak and strong El Niño years, respectively (Fig. S1). Given the well documented effects of ENSO on southern African precipitation (i.e., decrease in precipitation amount) [Allan *et al.*, 2003; Nicholson and Entekhabi, 1986; Reason and Rouault, 2002], the 2014-2015 and 2015-2016 meteorological droughts could be El Niño related. However, the 2012-2013 meteorological drought occurred during an El Niño neutral year suggesting that the cause of this drought was different from that of the 2014-2016 droughts (Fig. 2, Table S2 and Fig. S1). Precipitation was highly seasonal over the sampling period with 89.4 – 99.5% of annual precipitation occurring during the rainy season, Oct-Apr (Table S3). About 55% of the annual precipitation in Windhoek occurs between Feb-Apr (late summer), with peak rainfall amounts and largest inter-annual variability occurring in February [Lu *et al.*, 2016]. However, according to the data presented here, with the exception of 2013-2014, less than 50% of annual precipitation occurred during late summer, suggesting droughts resulted in precipitation distribution anomalies over the area (Table S3). Consequently, peak rainfall amounts differed among the years: March for 2012-2013, February for 2013-2014 and January for 2014-2015 and 2015-2016. Interestingly, most precipitation during 2012-2013 occurred during late summer while for 2014-2015 and 2015-2016 this occurred during early summer (Oct-Jan) (Table S3). This difference in precipitation distribution among the drought years also suggests that the causes of these droughts, 2012-2013 and 2014-2016, were different with the 2012-2013 drought being the most severe (Figure 2 and Table S2).

[Figure 2 here]

3.2 Precipitation isotope ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$) variations

The long-term “2012-2016” weighted precipitation isotope compositions from this study (Table 1) were comparable to those from *Kazmierz Rozanski and Gonftanttni* [1993] ($\delta^{18}\text{O}$ -5.0‰) and the Online Isotopes in Precipitation Calculator (OIPC) ($\delta^{18}\text{O}$ -5.2‰ and $\delta^2\text{H}$ -27.0‰) [Bowen and Revenaugh, 2003; Bowen, 2017]. Similarly, the unweighted precipitation isotope compositions were comparable to those extracted from the Namibia precipitation isoscape ($\delta^{18}\text{O}$ -2.9‰ and $\delta^2\text{H}$ -12.6‰) [Kaseke *et al.*, 2016] and *Kazmierz Rozanski and Gonftanttni* [1993] ($\delta^{18}\text{O}$ -2.7‰) (Table 1). Therefore, the precipitation isotope results presented in this study are consistent with long term data presented elsewhere, thus comparisons of event scale with aggregated data may help define underlying uncertainties between isotopic compositions and climatic variables at longer time scales [Soderberg *et al.*, 2013].

Storm-to-storm isotopic variability over the four year period, $\delta^{18}\text{O}$ 25‰, $\delta^2\text{H}$ 180‰ and $\delta^{17}\text{O}$ 13‰, was similar to that reported elsewhere [Benson and Klieforth, 1989; Friedman *et al.*, 2002; Liu *et al.*, 2010] (Table 1). However, at annual scales storm-to-storm isotopic variation was lower for the meteorological drought years while those for the ‘normal year’ 2013-2014 were similar to the four year overall isotopic variability (Table 1). The 2013-2014 precipitation was significantly depleted in $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ (-5.97‰, -42.44‰, -3.14‰) compared to 2012-2013 (+0.94‰, +9.51‰, +0.48‰), 2014-2015 (-0.41‰, +1.73‰, -0.33‰) and 2015-2016 (-1.13‰, -5.36‰, -0.61‰) (One-way ANOVA, $p < 0.05$; Tukey’s post-hoc test, $p < 0.05$) (Table 1). This could be attributed to the ‘amount effect’ [Dansgaard, 1964], as both annual weighted and arithmetic mean precipitation isotope ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$) values were significantly inversely related to precipitation amount ($p < 0.05$, Fig. S2). One aspect of the ‘amount effect’ that could be important is sub-cloud evaporation [Salamalikis *et al.*, 2016]. In theory, drought conditions should enhance sub-cloud evaporation resulting in precipitation enrichment ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$), lower ranges and lower d compared to normal years (Table 1). However, d was similar among the years (Kruskal Wallis, $p > 0.05$) (Table 1) and also similar between the normal (+7.5‰) and drought years (+7.1‰) (Mann Whitney Pairwise test, $p > 0.05$), suggesting that the degree of sub-cloud evaporation during droughts and normal years at this semi-arid site may not differ significantly.

Theoretically, longer travel times would allow for more equilibration time of raindrops with sub-cloud vapour (isotopic exchange) and sub-cloud evaporation resulting in higher $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ values and lower d (Table 1). As expected, the median LCL for precipitation events during 2013-2014 (361 m) was significantly lower than that of the drought years (580 m) (Mann Whitney U, $p < 0.005$), indicating longer raindrop travel times from cloud base to the ground surface during droughts. To evaluate the degree of aridity effects between normal and drought years, d of drought and normal year precipitation events with LCL between 300 and 600 m (based on the median LCL) was evaluated. The d of drought year precipitation events (+10.2‰, range: -8.3‰ to +18.6‰) was significantly larger than for the normal year (+6.8‰, range: -5.2‰ to +15.4‰) (Mann Whitney Pairwise test, $p < 0.05$), suggesting that some other mechanism maybe influencing d within this bin and this could be attributed to enhanced moisture recycling during droughts in the Kalahari ecoregion. Although the Kalahari ecoregion experiences a volumetric decrease in precipitation during droughts, it is accompanied by an increase in the recycling ratio (28% vs. 34% during wet and drought years), defined as the terrestrially derived precipitation divided by the total precipitation [Miralles *et al.*, 2016]. In the Amazon Basin, evaporation (E) accounts for about 40% of the evapotranspiration (ET) flux and the resultant precipitation is characterised by $d > +10$ ‰, suggesting a significant part was derived from evaporation [Gat and Matsui, 1991; Martinelli *et al.*, 1996; Victoria *et al.*, 1991]. This might explain the precipitation events with

$d > +10\text{‰}$ observed in this study (Table 1). Therefore, the larger d during drought years ($+10.2\text{‰}$) in the 300–600 m LCL bin suggests an increase in the evaporative flux due to moisture recycling, indicating drier conditions for the region compared to the normal year ($+6.8\text{‰}$), whose d was probably influenced more by sub-cloud evaporation.

[Table 1 here]

3.3 Key local drivers of precipitation isotope compositions

Precipitation isotopes are governed by several factors including but not limited to evaporation processes at the source, precipitation type and subsequent rain-out processes along the air mass-trajectory; however, correlations with local meteorological parameters suggest possible modification at the precipitation site [Coplen *et al.*, 2015; Dansgaard, 1964; Fuderasu *et al.*, 2011; Rindsberger *et al.*, 1983; Salamalikis *et al.*, 2016; Yurtsever, 1975]. The Windhoek precipitation isotope data at both event and monthly scales, exhibited significant relationships with local meteorological conditions (Table 2 and Table S4, respectively). Whereas event-scale precipitation isotopes were related to more local meteorological parameters than monthly isotopes (6 parameters vs. 3 parameters), suggesting loss of information on individual events through data aggregation [Noone and Simmonds, 2002], these relationships were stronger at monthly scale [Risi *et al.*, 2008; Vimeux *et al.*, 2005; Wu *et al.*, 2015]. Therefore, event-scale comparisons with aggregated data will help define underlying uncertainties in relationships between isotopic composition of precipitation and climatic variables [Soderberg *et al.*, 2013].

[Table 2 here]

According to event-scale univariate analyses, the most significant local drivers of precipitation isotopes ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$) in decreasing order were RH, LCL, precipitation amount, surface temperature, average wind speed and air temperature (Table 2). Precipitation isotopes were inversely related to RH, which reflected the influence of sub-cloud evaporation on isotopic composition [Berkelhammer *et al.*, 2012; Salamalikis *et al.*, 2016] (Table 2). This result was consistent with the Namibia precipitation isoscape that identified RH as a key driver of precipitation isotopes across Namibia [Kaseke *et al.*, 2016]. Precipitation isotopes were positively related to LCL and this could be attributed to the raindrop travel time between the cloud base and ground surface, the longer this was the more time available for raindrop isotopic equilibration with sub-cloud vapor and sub-cloud evaporation [Salamalikis *et al.*, 2016; Sánchez-Murillo *et al.*, 2016] (Table 2). Because LCL is a function of temperature and RH; RH and LCL are related ($\text{RH} = -0.04(\text{LCL}) + 99.00$, $r = -0.999$, $r^2 = 0.998$, $p < 0.005$), and this underlies the inverse relationship between d and LCL (Table 2). Precipitation isotopes were also inversely related to precipitation amount and this could be attributed to the “amount effect” [Dansgaard, 1964]. The ‘amount effect’ suggests that light precipitation events are more prone to equilibration with enriched sub-cloud vapour and or experience sub-cloud evaporation and are thus more enriched than larger volume events. Larger precipitation events increase sub-cloud RH, reducing evaporation resulting in depleted isotope compositions compared to smaller events. This would result in positive relationships between d and precipitation amount and d and RH (Table 2). These results were thus

consistent with expected sub-cloud evaporation from low intensity precipitation events over Windhoek. Finally, precipitation isotopes ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$) showed weak but positive relationships with site air and surface temperature similar to *Treble et al.* [2005], which would enhance isotopic exchange with sub-cloud vapour as well as sub-cloud evaporation (Table 2). This was however, in contrast to *Dansgaard* [1964] who did not observe a temperature effect using monthly data for the site.

At monthly time-scales, the significant drivers of local precipitation isotope composition in decreasing order were RH, precipitation amount and minimum temperature ($p < 0.05$) (Table S4), while d was significantly related to a single local parameter RH (Table S4). Similar to the findings of *Dansgaard* [1964], volume weighted monthly precipitation isotope compositions detected the “amount effect” indicating much stronger relationships than either the unweighted event or monthly samples but did not detect the “temperature effect” (Table 2, Table S4 and Table S5). This suggests loss of information through data aggregation, “temperature effect”, [*Noone and Simmonds*, 2002], while at the same time indicating that aridity is a major driver of precipitation isotope compositions at the site. Similarly, the weighted LMWL slope for this study 7.9 ± 0.35 ($n=29$) was similar to that determined earlier 8 ± 1.5 ($n=14$) [*Dansgaard*, 1964], indicating sub-cloud evaporation and consistent with the interpretations above and classification of the site as semi-arid (*BSh*).

Because multi-scale influences on precipitation isotopes do not conform well to univariate regression analysis in mid-latitude and subtropical locations [*Alley and Cuffey*, 2001; *Fricke and O'Neil*, 1999; *Sturm et al.*, 2010], we applied multiple linear regression analysis (MLRA) at event scale (Table 3). The best performing models for $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ combined air temperature, precipitation amount and RH, accounting for 47-53% of isotope variability at the site (Table 3). However, the best performing model for d included precipitation amount, LCL and average wind speed and accounted for 55% of the variation (Table 3). These MLRA models explained more precipitation isotope variation at event-scale compared to univariate analyses giving credence to the view that precipitation isotopes at mid-latitude and subtropical locations do not lend well to univariate analysis (Table 2 and Table 3). At the same time, these MLRA models suggest significant local modification of the precipitation isotope composition such that d cannot be considered a conservative environmental tracer of evaporation conditions at the source, at least for this semi-arid site [*Lai and Ehleringer*, 2011; *Welp et al.*, 2012; *Zhao et al.*, 2014] (Table 3). However, it is important to acknowledge that no analyses of source conditions was performed in this study. The most influential local parameter on precipitation isotope compositions over Windhoek according to the MLRA models was RH, suggesting isotopic exchange and sub-cloud evaporation associated with cloud base to ground surface travel time enhanced by air temperature as the physical mechanism accounting for 47-53% of $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ variability. However, for d , LCL was the most influential parameter suggesting cloud base to ground surface travel time and associated sub-cloud evaporation with windy conditions as the driving physical mechanism (Table 2 and Table 3).

[Table 3 here]

The unaccounted precipitation isotope ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$) variability from the MLRA models could be related to several factors including but not limited to precipitation type, rain-out processes and source evaporation conditions [*Aggarwal et al.*, 2016; *Coplen et al.*, 2015; *Crawford et al.*, 2013; *Dansgaard*, 1964; *Fudeyasu et al.*, 2011; *Jouzel et al.*, 2013]. Recently, stratiform and convective precipitation have been associated with depleted

and enriched isotopic compositions, respectively [Aggarwal *et al.*, 2016; Coplen *et al.*, 2015; Fudeyasu *et al.*, 2011; Kurita, 2013]. However, no significant relationships were observed between $\delta^{18}\text{O}$, $\delta^2\text{H}$, $\delta^{17}\text{O}$ and stratiform fraction at our study site, suggesting isotopic composition was independent of precipitation type (Table S6). This was supported by the significant inverse relationship between d and stratiform fraction (Fig. 3a), suggesting stratiform precipitation was more susceptible to sub-cloud evaporation than convective precipitation. Stratiform precipitation consists of small raindrops (~1 mm in diameter) which may partially evaporate or grow by accretion and coalescence depending on prevailing conditions: subsidence or uplift, respectively [Houze Jr, 2014]. Convective precipitation on the other hand consists of larger rain drops (> 2 mm in diameter) that do not experience much evaporation or growth [Houze Jr, 2014; Schumacher and Houze Jr, 2003; Steiner and Smith, 1998]. Therefore, an increase in stratiform fraction would diminish raindrop size, increase travel time from cloud base to ground surface, decrease average precipitation rate facilitating sub-cloud evaporation and isotopic exchange with below cloud vapor. Models estimate a 30-80% reduction in raindrop size due to sub-cloud evaporation in arid environments, resulting from a combination of high temperatures and low RH [Wang *et al.*, 2016]. At the same time, the weighted precipitation rate decreased with an increase in stratiform fraction (Fig. 3b), consistent with the predictions above enhancing equilibration with ambient vapour as well as enhancing sub-cloud evaporation. This would result in lower d , and higher $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ values for stratiform compared to convective precipitation which is less susceptible to sub-cloud evaporation [Houze Jr, 2014; Schumacher and Houze Jr, 2003; Steiner and Smith, 1998], although this was only significant for d (Table S7).

Applying MLRA to d , the best performing model was $d = 4.0 - (0.12 * \text{stratiform fraction}) + (0.56 * \text{amount})$ (AIC 82.9, R^2 0.61, RMSE 5.3, $p < 0.05$), with precipitation amount being the most influential parameter. These results suggest that sub-cloud evaporation resulted in enrichment of ^{18}O , ^2H and ^{17}O in stratiform precipitation to the extent that it was more enriched or similar to convective precipitation at the site (Table S7). This would explain the observed $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ independence of precipitation type and rate observed at the site (Table S6). This contradicts the suggestion that the relationship between precipitation isotopes and intensity may be more visible at event scale [Dansgaard, 1964]. This result could be related to the fact that precipitation type and intensity are related (Fig. 3), thus where both types occur the influence of sub-cloud evaporation on the isotopic composition of the different precipitation types is not equal (Table S7). Therefore, the effect of precipitation intensity will likely be best observed when each precipitation type is considered separately or d is used instead (Table S6). However, given the data reduction already incurred in differentiating precipitation type, such an analysis is not possible for this study. These results, therefore suggest that precipitation isotopes are independent of precipitation type at least at this site and possibly other dryland environments. However, it is important to acknowledge the complexity associated with these calculations, notably estimation of stratiform fraction is greater when shallow rain is significant and amounts are low [Funk *et al.*, 2013; Schumacher and Houze Jr, 2003], while isotope data at a sampling point could be biased towards stratiform precipitation (point vs raster data) [Aggarwal *et al.*, 2016]. Nonetheless, these calculations provide general trends of precipitation isotopes and precipitation type in a semi-arid environment.

[Figure 3 here]

3.4 HYSPLIT air mass back trajectories, cluster analysis and $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slopes

Ten day HYSPLIT [Stein *et al.*, 2015] back-trajectory analyses suggest that Windhoek (2012-2016) precipitation originated from both the Indian and Atlantic Oceans (Fig. 4). However, the 140 hr trajectory cluster analysis grouped the sources into four clusters (Fig. 4), but no significant differences were detected among the precipitation clusters in $\delta^{18}\text{O}$, $\delta^2\text{H}$, $\delta^{17}\text{O}$ and d . This suggests precipitation isotopes underwent extensive modification at the precipitation site (47-53%) making them indistinguishable (Table 3). The results highlight the inappropriateness of d as a conservative tracer of evaporation conditions at the source region, as 55% of d variability was related to local meteorological conditions at the precipitation site (Table 3). However, $^{17}\Delta$ and $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ could be used as conservative tracers of humidity changes at the vapour source independent of temperature and thus complement d interpretations [Angert *et al.*, 2004; Barkan and Luz, 2007; Li *et al.*, 2015]. $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slopes of 0.529 ± 0.001 indicate a dominance of equilibrium fractionation processes, suggesting high RH conditions at the evaporation source [Luz and Barkan, 2005]. Therefore the $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slope of cluster 1 (0.529 ± 0.003) suggests high RH conditions over the subtropical Indian Ocean evaporation source (Fig. 4 and Fig. 5). However, $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slopes of 0.506-0.5185 indicate a dominance of kinetic fractionation processes suggesting non-steady state conditions with low RH at the evaporation source [Angert *et al.*, 2004; Barkan and Luz, 2007]. Thus the $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slopes of clusters 2 (0.502 ± 0.007) and 3 (0.507 ± 0.019) suggest low RH conditions over the South Atlantic during evaporation (Fig. 4 and Fig. 5). The $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slope for cluster 4 (0.520 ± 0.004) suggests non-steady state evaporative conditions at more than 50% RH [Li *et al.*, 2015]. It is important to note that these trajectories only indicate geographic origins of moisture and do not take in account any additional moisture picked during transport to the site. We acknowledge that there seems to be an association between trajectory distance and $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$, suggesting an influence of ET on $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ [Landais *et al.*, 2006; Li *et al.*, 2017] (Fig. 4). However, given that moisture recycling is estimated at 28-34% [Miralles *et al.*, 2016], how and to what extent ET would influence precipitation $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ in the region is uncertain [Landais *et al.*, 2006; Li *et al.*, 2017] and beyond the scope of the current study.

[Figure 4 here]

[Figure 5 here]

The origins of cluster 1 were consistent with the position of the Subtropical Indian Ocean dipole (SIOD) [Reason, 2001] while cluster 4 origins were consistent with the position of the tropical Indian Ocean dipole (IOD) (Fig. 4). Sea surface temperatures (SST) around the origins of cluster 1 range from 23-26°C while those around cluster 4 origins range from 24-28°C (Oct-Apr) [Rao *et al.*, 1989]. Warmer SSTs would result in greater evaporation and result in higher RH over the tropical oceans (30°N-30°S) [Shie *et al.*, 2006]. However, the $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slope of cluster 4 (0.520) was smaller than that of cluster 1 (0.529) despite higher SST around cluster 4 origins. This suggests non-steady state conditions around cluster 4, resulting in lower RH than expected from the SST compared to cluster 1 origins. Summer precipitation in southern Africa has been associated with the tropical western Indian Ocean with the subtropical southwest Indian Ocean thought to be a substantial source of moisture for the region [D'Abreton and Lindesay, 1993; Reason and Mulenga, 1999]. However, the

trajectory analyses results suggest that the subtropical Indian Ocean may contribute more moisture over the western parts of southern Africa or at least Windhoek (2012-2016) than the tropical Indian Ocean (Fig. 4).

The third potential source of moisture associated with summer precipitation over southern Africa is often regarded as the tropical South Atlantic Ocean [Fauchereau *et al.*, 2003; Hermes and Reason, 2005], although exact influences are unknown [Reason *et al.*, 2006]. However, our results suggest that clusters 2 and 3 originated from a region over the subtropical South Atlantic Ocean (Fig. 4). It is known that West African precipitation is influenced by a South Atlantic Ocean dipole (SAOD), defined as: north east pole, NEP (10°E–20°W, 0°S–15°S) and south west pole, SWP (10°W–40°W, 25°S–40°S) [Nnamchi and Li, 2011; Nnamchi *et al.*, 2011]. However, simulations of this SAO also suggest a smaller south-east pole (SEP) in phase with the NEP [Nnamchi *et al.*, 2011], consistent with the origins of clusters 2 and 3, defined as SEP 0°E–15°E and 30°–45°S (Fig. S4). However, because Nnamchi and Li [2011] focussed on SAOD influences on precipitation variability in West Africa, no attention was paid to possible influences on precipitation variability in southern Africa. Given that the results presented here and the simulations by Nnamchi *et al.* [2011] converge over the same region, suggests this SEP could be an extension of the SAOD or a secondary subtropical SAOD defined as SEP and SWP and may influence precipitation variability in southern Africa, at least over Windhoek (Fig. S4). However, Reason and Jagadheesha [2005] and Harris *et al.* [2010] also suggest the existence of a subtropical South Atlantic Ocean dipole influencing precipitation over the Southwestern Cape region of South Africa, although the location of the dipole is shifted slightly to the left of that proposed in Figure S4. Therefore, the existence of a subtropical South Atlantic Ocean dipole is a distinct possibility although exact locations may be debatable and outside the scope of this study. This is in contrast to studies that have often exclusively associated precipitation anomalies over western parts of central and southern Africa to the tropical South Atlantic Ocean, Benguela Niño and the South Atlantic Ocean Dipole (SAOD) [Hermes and Reason, 2005; Nnamchi and Li, 2011; Reason and Smart, 2015; Rouault, 2003].

Applying a simple classification based on oceanic origins of precipitation events over Windhoek (2012-2016), precipitation events were grouped into two: Indian Ocean (clusters 1 and 4) and subtropical Atlantic Ocean (clusters 2 and 3) (Fig. 4 and Fig. 6). The resulting $\delta^{17}\text{O}-\delta^{18}\text{O}$ slope for precipitation from the subtropical Atlantic Ocean (0.506 ± 0.009) was consistent with dominance of kinetic fractionation processes ($0.506-0.5185$), suggesting evaporation under non-steady state conditions at low RH [Angert *et al.*, 2004; Barkan and Luz, 2007; Li *et al.*, 2015] (Fig. 6a). The $\delta^{17}\text{O}-\delta^{18}\text{O}$ slope for precipitation from the Indian Ocean (0.525 ± 0.002) was close to the 0.5265 slope which indicates evaporation occurred at high RH ($\sim 85\%$) [Li *et al.*, 2015] (Fig. 6b). According to Araguás-Araguás *et al.* [2000], high RH ($\sim 80\%$), warm temperatures (25°C) and low wind velocities result in d values of about $+10\text{‰}$. Therefore, the $\delta^{17}\text{O}-\delta^{18}\text{O}$ results were consistent with SST and RH conditions for the Indian Ocean [Araguás-Araguás *et al.*, 2000; Rao *et al.*, 1989]. However, precipitation d from the Indian ($+7.7\text{‰}$) and subtropical Atlantic Oceans ($+5.5\text{‰}$) were significantly smaller than the GMWL ($+10\text{‰}$) (Kruskal-Wallis, $p < 0.05$; Mann-Whitney post-hoc test, $p < 0.05$). There were no significant differences between precipitation d from the Indian and subtropical Atlantic Oceans (Kruskal-Wallis, $p > 0.05$) nor between their respective LMWLs (One-way ANCOVA, $p > 0.05$) (Fig. 6c and Fig. 6d). These results suggest precipitation isotopes collected in Windhoek underwent significant modification by local meteorological conditions, consistent with earlier conclusions (Table 2 and Table 3). These local modifications, resulted in similar LMWLs (Fig. 6c and Fig. 6d) and may have altered precipitation d by as much as 55% such that its use as a conservative tracer of evaporation

conditions at the source may be questionable, at least for this semi-arid environment (Table 3).

[Figure 6 here]

Precipitation from the subtropical Atlantic Ocean was significantly enriched in $\delta^{18}\text{O}$ (+0.8‰), $\delta^2\text{H}$ (+12.7‰) and $\delta^{17}\text{O}$ (+0.5‰) than from the Indian Ocean $\delta^{18}\text{O}$ (-2.0‰), $\delta^2\text{H}$ (-9.9‰) and $\delta^{17}\text{O}$ (-0.9‰) (Kruskal-Wallis, $p < 0.05$). Because the Atlantic Ocean (~266 km) is located closer to Windhoek than the Indian Ocean (~1904 km) (Fig. 1 and Fig. 4), the observed precipitation enrichment in $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ from events originating from the subtropical Atlantic Ocean could be reflecting the ‘continental effect’ [Dansgaard, 1964]. In addition, the isotope compositions of precipitation originating from the subtropical Atlantic Ocean presented here were generally more enriched in $\delta^{18}\text{O}$ and $\delta^2\text{H}$ compared to those reported for Cape Town [Harris *et al.*, 2010]. This could be attributed to the influence of sub-cloud evaporation at Windhoek as noted by Dansgaard [1964].

The Indian Ocean trajectories were the dominant source of Windhoek precipitation during 2012-2016, accounting for 68-92% of annual precipitation events and 51-94% of the annual precipitation amount (Table 4). These results were consistent with studies that have concluded that the Indian Ocean was the primary source of moisture for precipitation over southern Africa [D'Abreton and Lindesay, 1993; Reason and Mulenga, 1999; Reason and Smart, 2015]. On the other hand, the results also indicate that the South Atlantic Ocean trajectories contributed a substantial amount of precipitation to Windhoek during this period; 24-32% of annual precipitation events and 10-49% of annual precipitation amount during drought years and 6-8% during non-drought years (Table 4). Therefore, more research is needed to understand the influence and effects of the sub-tropical South Atlantic Ocean on precipitation in Windhoek, Namibia and southern Africa. It is important to acknowledge that the temporal isotopic variability for this subtropical semi-arid site (Table 1) is similar to that of tropical sites e.g., Puerto Rico with different moisture sources [Sánchez-Murillo *et al.*, 2016], suggesting some other pan-tropical mechanism may influence precipitation isotope compositions in addition to those described by [Dansgaard, 1964]. Aggarwal *et al.* [2016] suggests that this mechanism could be the precipitation type, however, the results presented here contradicted this, suggesting that if such a pan-tropical mechanism exists, it requires further investigations.

[Table 4 here]

3.5 Annual and inter-annual local meteoric water lines (LMWL)

Figure 7 displays the different LMWLs generated for the site based on 2012-2016 event-scale data from the Local Meteoric Water Line Freeware programme [Crawford *et al.*, 2014]. Crawford *et al.* [2014] notes that the calculation of LMWLs using different methods on the same data can result in wildly different LMWLs, complicating interpretation. However, for this particular site LMWLs based on the unweighted methods were similar while those based on the weighted versions were similar while both showed the same trends. The weighted LMWLs had larger slopes and intercepts than the unweighted LMWLs (Fig. 7). However,

these LMWLs were similar to those calculated for Windhoek based on GNIP data, $y = 7.1013x + 8.0159$ (OLSR) and $y = 7.30x + 9.3594$ (PWLSR) [Crawford *et al.*, 2014], except for the lower intercepts. The slope of the OLSR 2012-2016 LMWL (7.05) was significantly smaller than the global meteoric water line (GMWL) (8) (ANCOVA, $p < 0.05$) while GMWL d (+10‰) was significantly larger than that of the 2012-2016 Windhoek LMWL (+7.1‰) (Kruskal-Wallis, $p < 0.05$) (Fig. 6). Local meteoric water lines with slopes < 8 are characteristic of arid and semi-arid environments [Araguás-Araguás *et al.*, 2000], consistent with the classification of Windhoek as a hot semi-arid climate (BSh). Arid and semi-arid environments also suggest secondary processes such as sub-cloud evaporation [Ehhalt *et al.*, 1963; Stewart, 1975], consistent with the low d observed at the site (Table 1).

[Figure 7 here]

Whereas the 2012-2016 Windhoek LMWLs gave an overview of the general climate characteristics, they did not reflect annual variability e.g., wet vs. dry years (Fig. 8 and Table S1). There was no significant difference between the OLSR 2012-2016 LMWL (7.05) and 2013-2014 LMWL (7.36) slopes, suggesting ‘normal’ precipitation amounts for the site during 2013-2014 (ANCOVA, $p > 0.05$) (Fig. 8b). However, the slopes of the OLSR LMWLs for 2012-2013 (6.57), 2014-2015 (6.42) and 2015-2016 (6.53) were significantly smaller than that of the 2012-2016 LMWL (7.05) (ANCOVA, $p < 0.05$) (Fig. 8). The deviation of these annual LMWL slopes below the 2012-2016 LMWL reference suggest below ‘normal’ precipitation during these periods at the site, consistent with the meteorological droughts observed (Fig. 2 and Table S2). These results suggest that meteorological droughts caused abnormally dry conditions beyond the normal arid or semi-arid conditions at the site. This would have resulted in enhanced or intense sub-cloud evaporation, significantly lowering annual LMWLs than the 2012-2016 LMWL (Fig. 8). Therefore the annual LMLs for 2012-2013, 2014-2015 and 2015-2016 were consistent with the cumulative precipitation totals which indicated meteorological drought conditions during these years (Fig. 2 and Table S2).

[Figure 8 here]

3.6 Drought differentiation using $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ relationship

There were no significant differences in precipitation d among the years 2012-2013 (+3.64‰), 2013-2014 (+7.33‰), 2014-2015 (+9.00‰), and 2015-2016 (+7.62‰) nor with the 2012-2016 LMWL (+7.13) (Kruskal-Wallis, $p > 0.05$). This suggests that the precipitation isotopes were significantly altered by the local environmental parameters such that d was not a conservative tracer of evaporation conditions at the source. At the same time, there were no significant differences between LMWLs generated from precipitation events from the Indian Ocean ($y = 7.14 \pm 0.13x + 2.11 \pm 0.97$; $r^2 = 0.98$, $p < 0.05$) and those from the subtropical Atlantic Ocean ($y = 6.78 \pm 0.35x + 4.78 \pm 1.2$; $r^2 = 0.95$, $p < 0.05$) (One-way ANCOVA, $p > 0.05$), suggesting that origins of precipitation had no effect on isotopic composition at the site. The $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slopes for 2012-2013 and 2013-2014 were similar (Fig. 9a and Fig. 9b), suggesting high RH (~85%) evaporation conditions [Araguás-Araguás *et al.*, 2000; Li *et al.*, 2015] conducive for mass transport of moisture to the precipitation site

(Fig. 1). While Windhoek received normal to above normal precipitation during 2013-2014 consistent with expectations of an El Niño neutral year, 2012-2013 was a drought (Fig. 2 and Fig. S1). However, the eastern and parts of central southern Africa (e.g., Mozambique, Zimbabwe, Botswana) experienced above normal precipitation and violent storms during 2012-2013 [Moyo and Nangombe, 2015] while the western parts including Namibia experienced droughts. This suggests Windhoek should have received normal to above normal precipitation during 2012-2013 but mesoscale (western southern Africa) conditions may have caused the drought. On the other hand, 2014-2015 and 2015-2016 $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slopes were similar (Fig. 9c and Fig. 9d) and suggested low RH (~50%) non-steady state evaporation conditions at the sources [Li *et al.*, 2015], conditions that would have resulted in less moisture transported to the precipitation site (Fig. 1). The 2014-2015 and 2015-2016 $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ slopes thus possibly reflected El Niño (Fig. S1), a synoptic system associated with droughts in the region [Hoell *et al.*, 2016]. Because 2012-2013 was ENSO neutral while the 2014-2016 droughts were probably El Niño related, $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ could be reflecting differences in the causes of these droughts; mesoscale vs. synoptic scale respectively (Fig. 9). These results were consistent with the increase (decrease) in recycled E/ET (T/ET) during 2014-2016 due to consecutive droughts that affected the entire region compared to the 2012-2013 drought which only affected the western parts of Southern Africa (Table S4). Interestingly, the origins of clusters 1 and 4 (Indian Ocean) were consistent with modelled source areas of precipitation deficits during droughts in the Kalahari ecoregion while clusters 2 and 3 (Atlantic Ocean) are not affected during droughts [Miralles *et al.*, 2016] (Fig. 4). This decrease in Indian Ocean contributions to precipitation could account for the percentage increase in South Atlantic Ocean contributions during droughts observed at Windhoek (Table 4).

[Figure 9 here]

Because the correlation between $\delta^{18}\text{O}$ and $\delta^2\text{H}$ is controlled by underlying physical properties, it has been argued that PWRMA and PWMA are more appropriate approaches than OLSR, especially the former [Crawford *et al.*, 2014]. According to the PWRMA and PWMA LMWLs, the meteorological drought severity increased in the following order 2014-2015, 2015-2016 and 2012-2013 (Table S1). However, this was in contrast to the precipitation totals which suggest drought severity increased in the following order 2015-2016, 2014-2015 and 2012-2013 (Fig. 2 and Table S2). Given the relationship between El Niño and droughts in the region [Allan *et al.*, 2003; Nicholson and Entekhabi, 1986; Reason and Rouault, 2002], the 2015-2016 drought was expected to be more severe than the 2014-2015 based on El Niño strength (Fig. S1). However, recent work suggests that precipitation response to drought in the region is related to ENSO and SIOD phase relationships [Hoell *et al.*, 2016]. A positive SIOD is characterized by warm waters on the south west Indian Ocean and cool tropical waters in the central and eastern Indian Ocean while a negative SIOD is reversed [Behera and Yamagata, 2001; Hoell *et al.*, 2016; Reason, 2002]. The warm waters of a positive SIOD increase evaporation and the moist air is advected over southern Africa [Behera and Yamagata, 2001; Reason, 2001]. When ENSO and SIOD are in phase(++), El Niño induced droughts are moderate but when ENSO and SIOD are antiphase (+-), El Niño induced droughts are severe [Hoell *et al.*, 2016]. During early summer 2014-2015, El Niño and SIOD were antiphase (Fig. S1 and Fig. S3) and this may have enhanced the precipitation response to El Niño, less precipitation than expected (Fig. 2 and Table S2). On the other hand, 2015-2016 experienced a stronger ENSO (+) but was in phase with the SIOD (+) (Fig.

S1 and Fig. S3) mitigating the precipitation response to El Niño, more precipitation than expected (Fig. 2 and Table S2).

Neither univariate analyses nor MLRA showed any significant relationships between precipitation amount, ONI and the SIOD as measured by the South Western Indian Ocean (SWIO) index (<http://stateoftheocean.osmc.noaa.gov/sur/ind/swio.php>) [OOPC, 2016] ($p > 0.05$). This could be because ENSO is a result of complex interactions between several climate systems, thus the multivariate ENSO index (MEI) (<https://www.esrl.noaa.gov/psd/enso/mei/table.html>) [NOAA, 2016] was substituted for ONI. MEI is considered the most representative ENSO index integrating multiple meteorological parameters measured over the Pacific Ocean [Mazzarella *et al.*, 2013]. Multiple linear regression analyses showed a significant relationship ($p < 0.05$) between precipitation amount, MEI and SWIO accounting for 17.4% of precipitation variability observed in Windhoek (2012-2016) (Table 5). These results suggest precipitation amount over the site may have been partly related to the interaction of the SIOD and ENSO nodes, consistent with [Hoell *et al.*, 2016] (Fig. 2, Fig. S1 and Fig. S3). We did not perform a similar analysis for the South Atlantic Ocean (SAO) because the north-eastern pole of the current SAO dipole indices are based on the north-eastern parts of the South Atlantic (<http://stateoftheocean.osmc.noaa.gov/sur/atl/sat.php>) [Nnamchi *et al.*, 2011; OOPC, 2017] versus the south eastern parts identified in this study (Fig. S4). Therefore the current South Atlantic Ocean Dipole (SAOD) Index does not represent the region of interest and is thus inappropriate for this study (Fig. S4). Furthermore, there is little research related to the influence of the subtropical Atlantic on precipitation across southern Africa.

[Table 5 here]

4 Conclusions

Precipitation isotopes sampled from Windhoek over the period 2012-2016 suggest significant modification by local meteorological parameters, accounting for 47-53% of the isotope variability. The most influential local meteorological parameters at both event and monthly scales indicated substantial sub-cloud evaporation at the site, consistent with the semi-arid classification of the site and the meteorological droughts that occurred during this period. At the same time, sub-cloud evaporation may have resulted in significant modification of stratiform precipitation such that it was indistinguishable from convective precipitation using individual isotopes, resulting in isotopic compositions ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$) that were independent of precipitation type. This suggests that precipitation $\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$ in arid and semi-arid environments could be independent of precipitation type, at least for Windhoek. However, it is still possible to differentiate stratiform precipitation from convection precipitation based on d . Trajectory analyses suggested that precipitation events experienced at the site could be broadly classified into two groups: Indian and subtropical South Atlantic Ocean sourced. Contrary to popular perception, these results suggest that the subtropical South Atlantic Ocean generates a non-negligible amount of precipitation events over Windhoek. Therefore the influence of the subtropical South Atlantic Ocean on southern African precipitation and climate could currently be underestimated. At the same time, $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ in conjunction with HYSPLIT back trajectories identified four precipitation source clusters. Two of these cluster sources were consistent with the positions of the Indian Ocean dipole and the subtropical Indian Ocean dipole while the remaining clusters had similar origins in the subtropical South Atlantic Ocean, consistent with simulations of a possible

dipole in the subtropical South Atlantic Ocean [Nnamchi *et al.*, 2011]. If such a dipole exists, this could influence precipitation over southern Africa and understanding it would improve forecasting efforts over the region or at least Windhoek and parts of South Africa. $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ appeared a much better tracer of environmental conditions at the evaporation site than d which was significantly influenced by meteorological conditions at the precipitation site. At the same time, $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ appeared to reflect differences between El Niño and non-El Niño related droughts, suggesting $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ could be a novel tool to differentiate drought causes; synoptic vs. mesoscale, respectively. Finally, the temporal isotope variability exhibited by this semi-arid site to tropical sites suggests pan-tropical mechanisms may be controlling precipitation isotope compositions but the nature of this mechanism we believe is still elusive.

Acknowledgements

Funding for this work was made available from the U.S. National Science Foundation (IIA-1427642 and EAR-1554894). The data used are listed in the references, tables and in supplementary Table S1. We thank three anonymous reviewers for their insightful comments and constructive suggestions to improve the quality of this manuscript.

Table 1. Annual weighted and arithmetic mean isotope ($\delta^{18}\text{O}$, $\delta^2\text{H}$ and $\delta^{17}\text{O}$) compositions of Windhoek precipitation (2012-2016) based on the hydrologic year, Oct-Sept.

Period	n	Mean $\delta^{18}\text{O}\text{‰}$			Mean $\delta^2\text{H}\text{‰}$			Mean $\delta^{17}\text{O}\text{‰}$			Mean $d\text{‰}$	
		Arith.	WA	Range	Arith.	WA	Range	Arith.	WA	Range	Arith.	Range
2012-2013	26	+0.94	-1.83	-9.74 - +7.36	+9.51	-7.55	-60.11 - +57.36	+0.48	-0.96	-5.36 - +4.03	+2.0	-18.9 - +18.6
2013-2014	37	-5.97	-9.03	-15.84 - +8.30	-42.44	-63.99	-122.19 - +51.98	-3.14	-4.76	-8.24 - +4.12	+5.3	-17.3 - +15.4
2014-2015	19	-0.41	-3.19	-9.80 - +9.31	+1.73	-15.48	-71.10 - +56.00	-0.33	-1.76	-5.38 - +4.69	+5.0	-36.2 - +19.8
2015-2016	27	-1.13	-2.83	-12.39 - +7.92	-5.36	-14.39	-85.29 - +48.21	-0.61	-1.46	-6.43 - +4.10	+3.6	-32.3 - +14.9
2012-2016	109	-2.15	-5.17	-15.84 - +9.31	-13.16	-33.00	-122.19 - +57.36	-1.16	-2.73	-8.24 - +4.69	+4.0	-36.2 - +19.8

Note: Arith. is arithmetic mean and WA is weighted average.

Table 2. Significant relationships between event precipitation isotopes ($\delta^{18}\text{O}$, $\delta^2\text{H}$, $\delta^{17}\text{O}$ and d) and local meteorological data from the National Botanic Research Institute (NBRI), Windhoek 2012-2016.

	Regression equation	r	R ²	p-value
$\delta^{18}\text{O}$	y = -0.24 * (relative humidity) + 15.12	-0.63	0.39	**
	y = 0.01 * (lifted condensation level) - 8.79	0.61	0.37	**
	y = -0.25 * (precipitation amount) - 0.03	-0.42	0.18	**
	y = 0.39 * (surface temperature) - 13.47	0.29	0.08	**
	y = 1.11 * (wind speed) - 6.37	0.24	0.06	*
	y = 0.56 * (air temperature) - 13.27	0.24	0.06	*
$\delta^2\text{H}$	y = -1.56 * (relative humidity) + 98.22	-0.56	0.31	**
	y = 0.06 * (lifted condensation level) - 55.44	0.54	0.29	**
	y = -1.69 * (precipitation amount) + 1.23	-0.39	0.15	**
	y = 8.62(wind speed) - 45.29	0.26	0.07	*
	y = 2.47(surface temperature) - 83.02	0.25	0.06	*
$\delta^{17}\text{O}$	y = -0.13(relative humidity) + 7.86	-0.62	0.39	**
	y = 0.005 (lifted condensation level) - 3.71	0.61	0.37	**
	y = -0.13(precipitation amount) - 0.06	-0.42	0.18	**
	y = 0.21(surface temperature) - 7.06	0.29	0.08	**
	y = 0.58(wind speed) - 3.37	0.24	0.06	*
	y = 0.29(air temperature) - 6.94	0.24	0.06	*
d	y = -0.21 (lifted condensation level) + 14.89	-0.68	0.47	**
	y = 0.40(relative humidity) - 22.71	0.68	0.47	**
	y = -1.78(air temperature) + 38.97	-0.50	0.28	**
	y = 0.34(precipitation amount) + 1.49	0.40	0.16	**
	y = -0.73(surface temperature) + 24.76	-0.37	0.14	**

Note: * denotes significance at $p < 0.05$ and ** denotes significance at $p < 0.005$.

Table 3. Best performing multiple linear regression models between event precipitation isotopes and local meteorological data from the National Botanic Research Institute (NBRI), Windhoek 2012-2016. Only meteorological conditions with significant relationships from Table 2 were used.

	Multiple linear regression equation	AIC	RSME	R ²	p-value
$\delta^{18}\text{O}$	$y = 43.26 - (1.03 \cdot \text{air temp}) - (0.01 \cdot \text{amt}) - (0.34 \cdot \text{RH})$	300.9	4.5	0.53	< 0.05
$\delta^2\text{H}$	$y = 334.28 - (8.62 \cdot \text{air temp}) - (0.70 \cdot \text{amt}) - (2.45 \cdot \text{RH})$	704.2	34.4	0.47	< 0.05
$\delta^{17}\text{O}$	$y = 22.67 - (0.54 \cdot \text{air temp}) - (0.06 \cdot \text{amt}) - (0.18 \cdot \text{RH})$	174.0	2.4	0.53	< 0.05
d	$y = 8.39 + (0.13 \cdot \text{amt}) - (0.02 \cdot \text{LCL}) + (1.68 \cdot \text{winspd})$	364.9	6.2	0.55	< 0.05

Note: air temp is air temperature (°C), RH is relative humidity (%), amt is precipitation amount, LCL is lifted condensation level and winspd is wind speed (ms⁻¹).

Table 4. Annual and total contribution of events and precipitation from the Indian and South Atlantic Ocean over Windhoek 2012-2016.

	2012 – 2013*		2013 - 2014†		2014 – 2015*		2015 – 2016*		2012 - 2016	
	Indian	Atlantic	Indian	Atlantic	Indian	Atlantic	Indian	Atlantic	Indian	Atlantic
% frq	71	29	92	8	76	24	68	32	79	21
% ppt	67	33	94	6	90	10	51	49	79	21

Note: frq (frequency), ppt (precipitation amount), * drought year and † non-drought year.

Table 5. Multivariate analysis of Windhoek precipitation as influenced by El Niño Southern Oscillation (ENSO) and the South Western Indian Ocean (SWIO) Index nodes (2012-2016).

	Multiple linear regression equation	AIC	RSME	R ²	p-value
ppt (mm)	$y = 27.61 - (15.32 \cdot \text{MEI}) + (37.07 \cdot \text{SWIO})$	337.3	32.6	0.17	< 0.05

Note: ppt is monthly precipitation amount

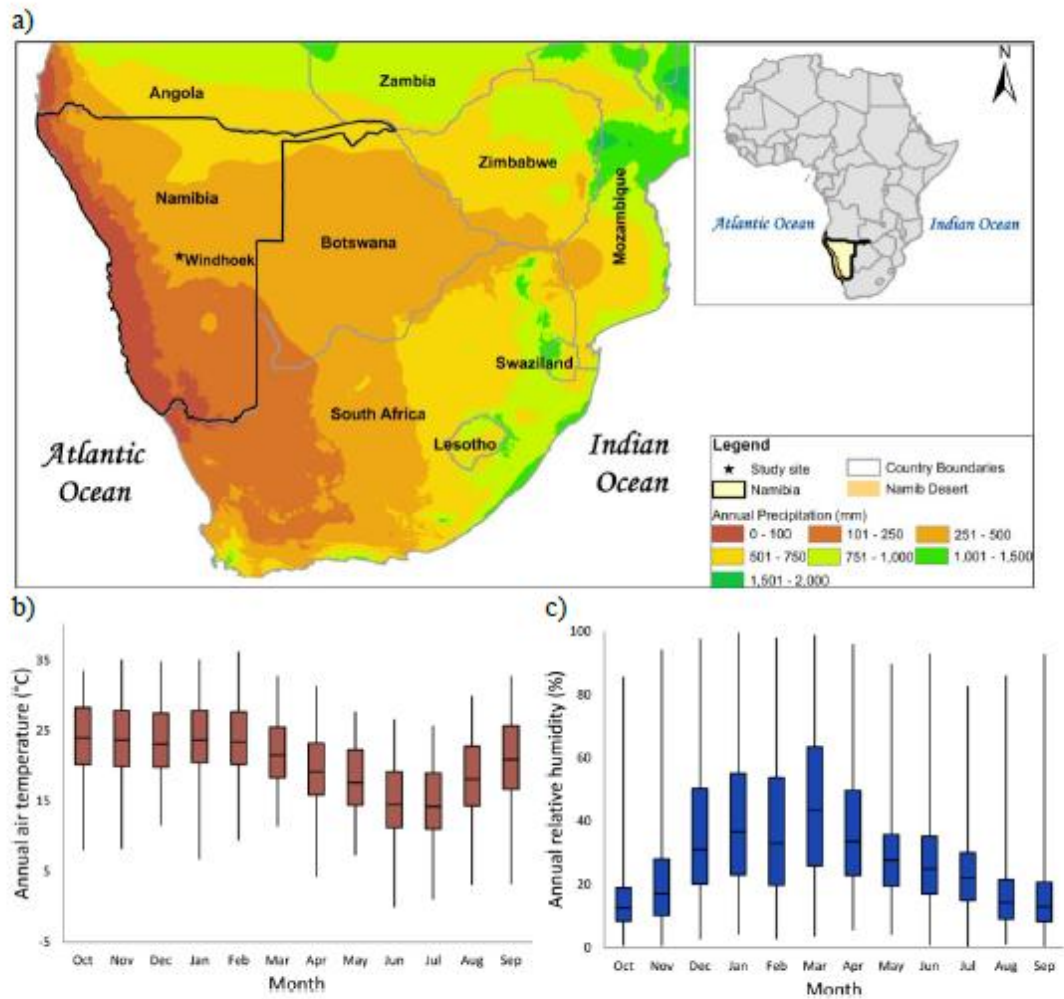

Figure 1. a) Map showing regional mean annual precipitation (<http://www.worldclim.org/bioclim>), location of the study site and Namibia (insert), b) monthly temperature and c) monthly relative humidity for Windhoek (2012-2016). Median represented by dark line in box, while box represents 1st and 3rd quartile range. Whiskers indicate the maximum and minimum values per month.

Figure 2. Annual cumulative precipitation totals measured from the site for Windhoek 2012-2016 (Oct-Sept) compared to long-term average 'normal' precipitation from the Namibia Meteorological Services.

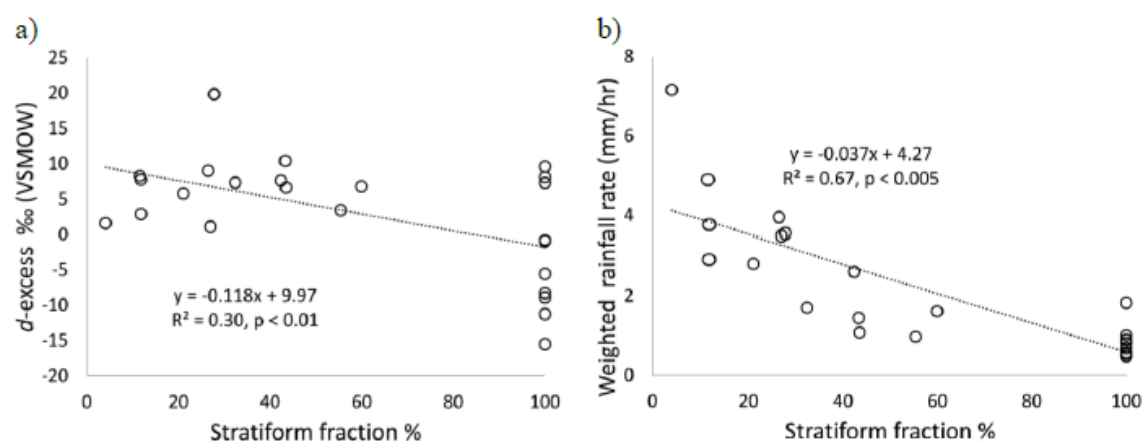

Figure 3. Variation of a) d -excess as a function of stratiform fraction and b) weighted conditional precipitation rate as a function of stratiform fraction, for rain events observed over Windhoek, 2012-2016 (n = 24).

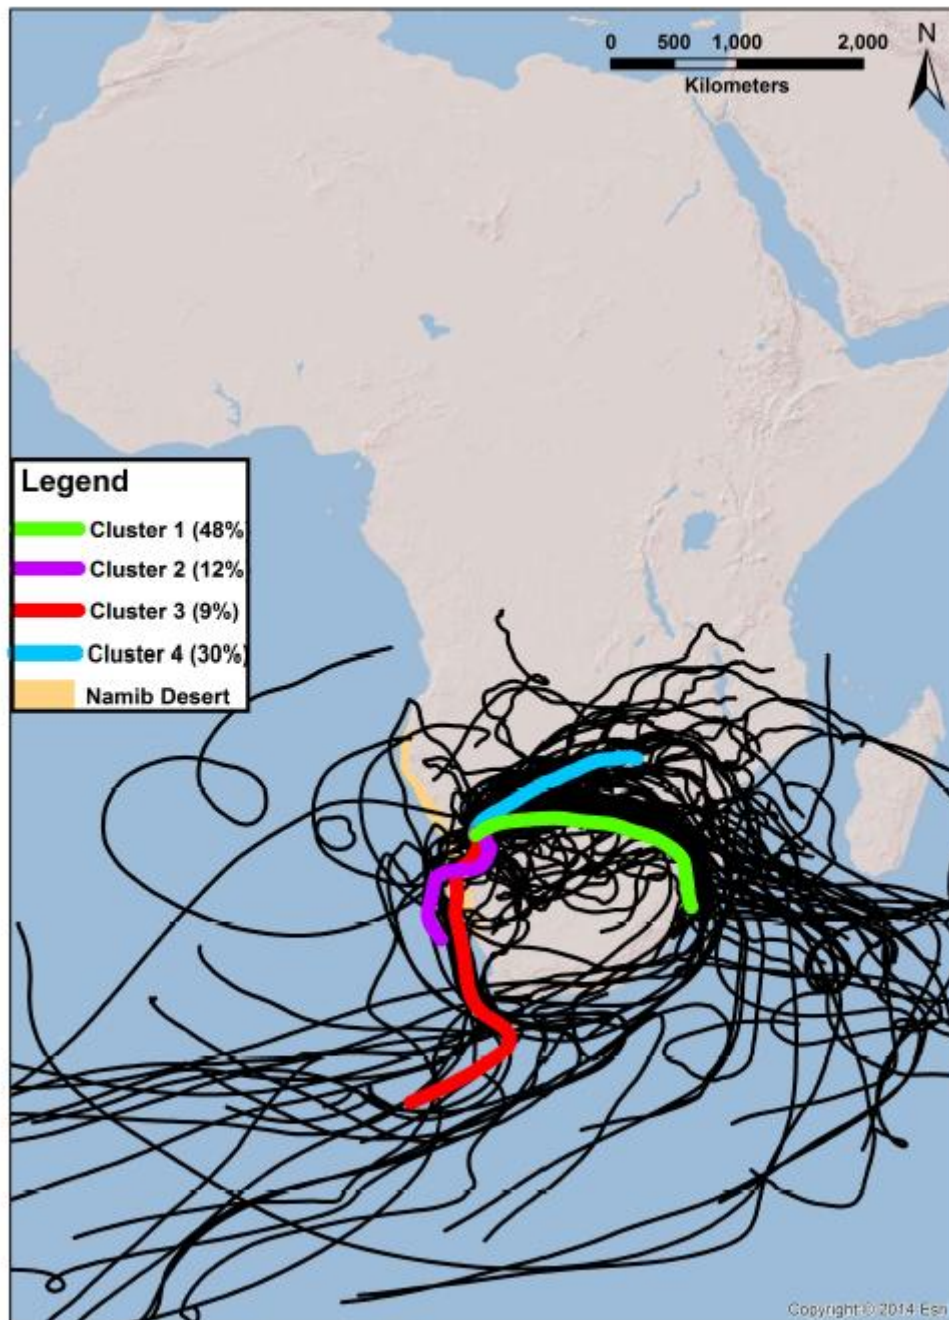

Figure 4. Ten day (240 hr) atmospheric back trajectories of precipitation events received at Windhoek during the 2012-2016 period ($n = 99$). The associated mean trajectory clusters were based on ~six day (140 hrs) trajectories, which equate to the approximate travel time to Windhoek after intersecting land and atmospheric residence times for the region [Miralles *et al.*, 2016].

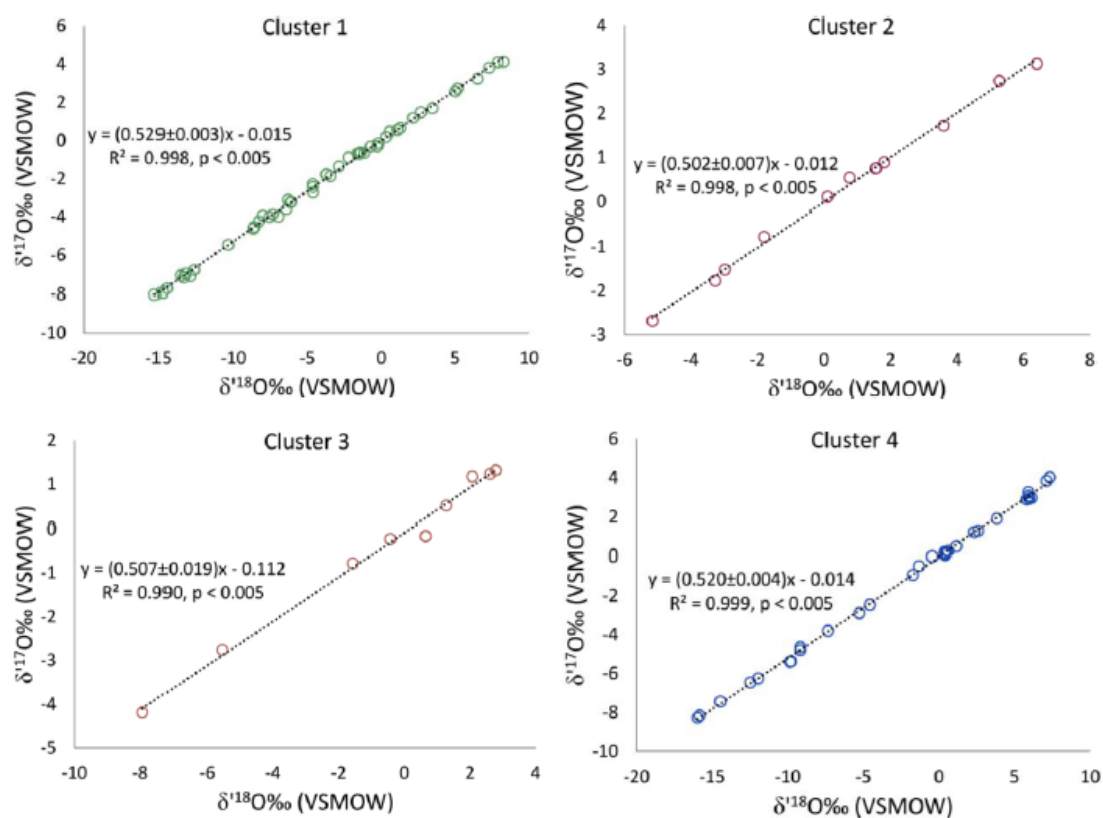

Figure 5. The four trajectory clusters of Windhoek precipitation during 2012-2016 as defined by the $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ relationships.

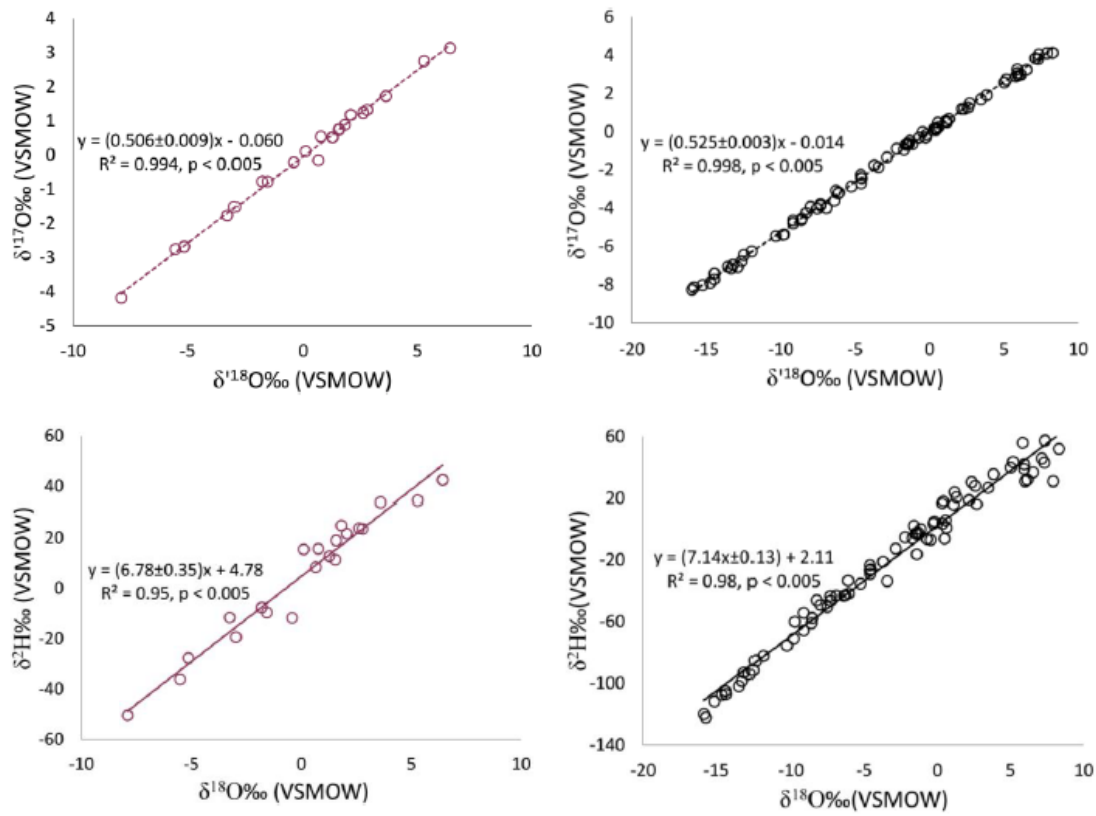

Figure 6. Isotope relationships of combined trajectory clusters based on ocean source for Windhoek precipitation 2012-2016; a) subtropical Atlantic Ocean $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$, b) Indian Ocean $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$, c) subtropical Atlantic Ocean $\delta^2\text{H}$ - $\delta^{18}\text{O}$ and d) Indian Ocean $\delta^2\text{H}$ - $\delta^{18}\text{O}$.

Figure 7. Event scale local meteoric water lines for Windhoek (2012-2016) calculated using [Crawford *et al.*, 2014] with the GMWL as a reference. Ordinary least square regression (OLSR), reduced major axis regression (RMA), major axis regression (MA) with precipitation weighted (PW) versions.

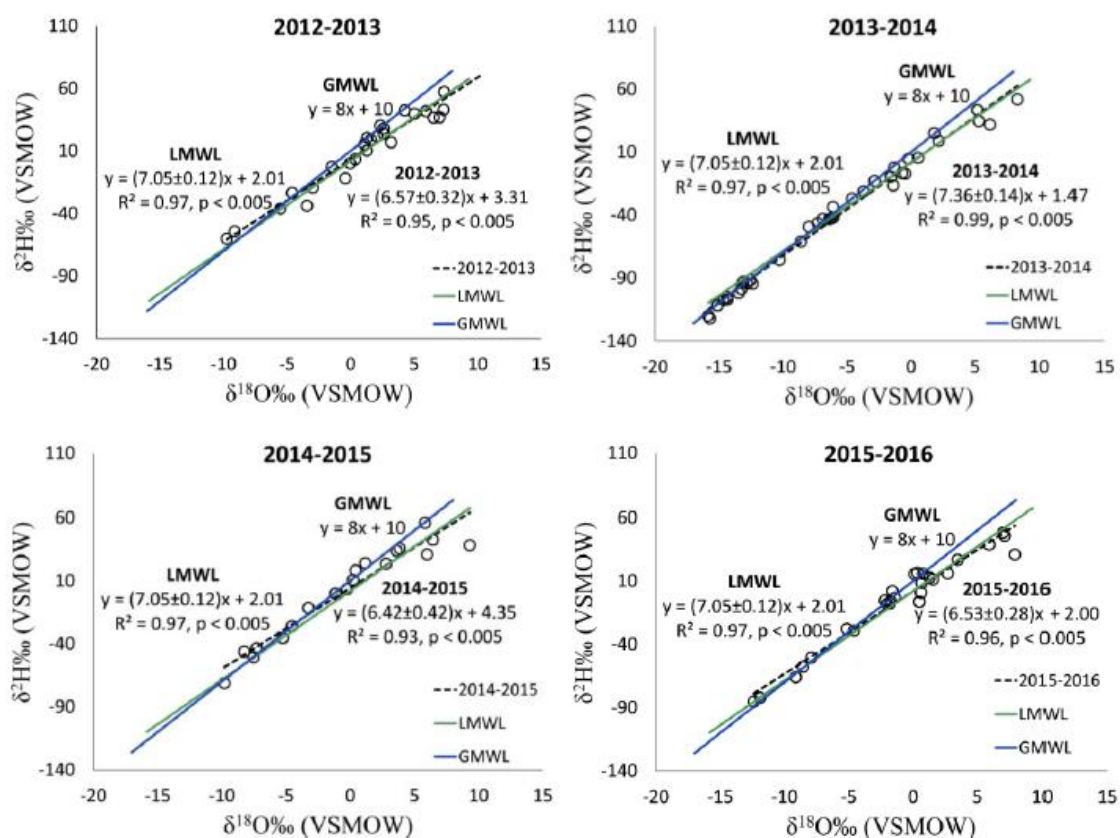

Figure 8. Annual unweighted local meteoric water lines (LMWLs) for Windhoek (2012-2016) based on the rainfall year (Oct-Sep): a) 2012-2013, b) 2013-2014, c) 2014-2015 and d) 2015-2016. The GMWL and unweighted LMWL(2012-2016) were included as references.

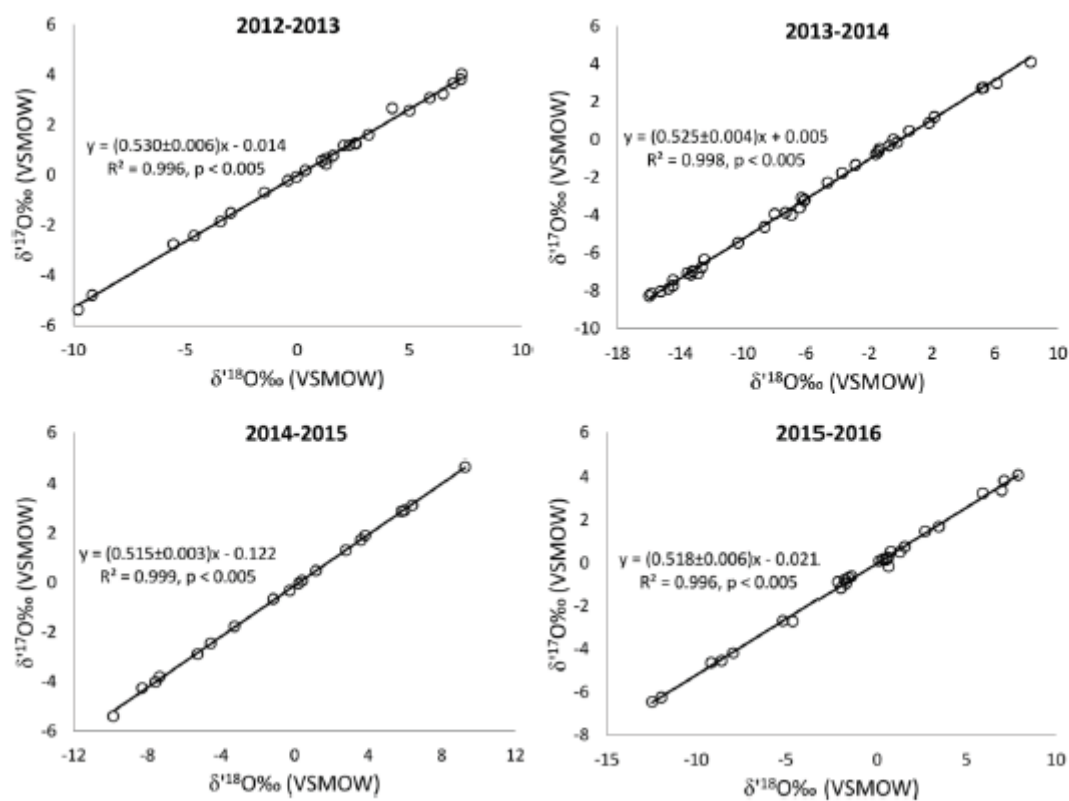

Figure 9. Plots showing the annual $\delta^{17}\text{O}$ - $\delta^{18}\text{O}$ of Windhoek precipitation over 4 years: a) 2012-2013, b) 2012-2013, c) 2013-2014 and d) 2014-2015.
